1.0 INTRODUCTION

1.1 Problem Statement and Summary

This report is concerned with the development of probabilistic performance data on levees and levee systems subject to multiple natural hazards. These probabilistic data are designed to fit into reliability and consequence scenarios useful in the making of decisions under uncertainty for the design or rehabilitation of levees from landslide, erosion, overtopping, subsidence, earthquake ground motion, and other hazards.

The key issue in the present study proved to be the estimation of probabilities of failure for an extended system (i.e., the probabilities of different levels of performance must be prescribed in terms of the extent of the levee system). It was found that the probabilistic failure analysis of a conventional slip circle landslide failure by itself is insufficient. Such analyses do not define the three dimensional extent of the failure and do not consider end effects. Vanmarcke (Ref. 1-1) solved this problem by considering a cylindrical failure surface and the correlation of material properties. Central to the three dimensional approach is the spatial correlation of material properties. This report extends the concepts of Vanmarcke to include an ellipsoidal failure surface, multi-layered levee geometry and several types of hazards.

The research presented in this report was primarily concerned with developing reasonable procedures to estimate system component probabilistic forecasts and then using these forecasts in a decision under uncertainty type of analysis involving the use of scenarios. It was found in practical engineering studies of an actual levee system that essential techniques are lacking in the rational presentation of probabilistic information to decision makers who are concerned with the portion of the levee that might fail, the extent of failure, the interactions of hazards, the time to failure, and the consequences of each likely failure sequence. It was also found that scenarios are a natural and expedient way in which to present the information.

1.2 Levee Types

In general there are two basic types of levee designs to consider:

- dry levees - levees which are in use only when a river overbanks (e.g., Mississippi River levees);
- wet levees - levees which are almost continually holding back water, although the water level may vary considerably (e.g., Sacramento-San Joaquin Delta levees).

Although they both are designed to withstand an extreme flood condition, their response to such flood conditions may be very different.

1.3 Report Organization

This report is organized as follows: Chapter 2 discusses the types of hazards and causes of failure of levee systems; emphasis is placed on natural causes. Chapter 3 discusses development of the three dimensional probabilistic stability model and its uses to study the effects of different hazards. Two general levee profiles were considered in the study. Profile C (Figure 1-1) is based on the idealized recommendation of the Corps of Engineers (Ref. 1-2). Profile W (Figure 1-2) was taken from an extensive geotechnical study of the levees of Woodward Island in the Sacramento-San Joaquin Delta area of California. These two profiles represent what are referred to as controlled and casual construction, respectively. Chapter 4 places the levee reliability problem in the context of systems analysis and decision makers in the process of designing or rehabilitating levee systems.

2. HAZARDS CAUSING FAILURE

2.1 Types of Failure

In general, a levee system is said to have failed when the protected area is flooded as a result either of water crossing the line of the levee from the riverside or water not being able to cross from the landside. The former failure can occur by overtopping from the riverside of the levee or by structural failure of the levee from hydrostatic pressure, piping, erosion, or earthquake. The latter failure can occur when accessorial facilities (i.e., pipes, pumps, ponds, and valves) fail to prevent flooding from interior drainage or through seepage.

2.1.1 Overtopping

Overtopping is caused by a flood stage which is higher than the levee crest height. Levee crest heights are usually designed to withstand specified peak flood stage plus a margin of safety which is based both on hydrologic and hydraulic considerations. However, what the designed crest height is and what the actual height is may differ considerably over time due to subsidence, erosion, compaction, etc. Levees which are poorly maintained will be more susceptible to overtopping over a period of time, because crest heights will decrease due to one or a combination of the above causes.

Flood stages for a given return period are uncertain. Hydrologic parameters used to predict discharge are based on limited historic records or on no historic data. Therefore, a level of uncertainty exists in these parameters. In addition, uncertainty exists in the hydrology of the flood. Although standard hydraulic techniques exist to predict flood profiles for given discharges, they are idealizations of a real world phenomenon which changes in time.

2.1.2 Stability

The stability failure of a levee at some location along the length is a problem in continuum mechanics, since the center of failure may occur anywhere along a reach, and the failure length can be almost any value within practical limits. In addition, the failure surface or zone of slippage may be any one of an infinite number of possibilities although failures may well be associated with a zone of weakness or a weak seam between two layers. Figure 2-1 illustrates the above three random variables, and indicates the continuum nature of each. To complicate the problem, the possible centers of failure, the lengths of failure, and the zones of slippage are all correlated to some degree with each other.

The conventional practice in evaluating existing levees is to look first at what are thought to be the weakest cross-sections, at least from the point of view of geometry. Soil samples are taken at these "weak" points and minimum factors of safety computed for a two-dimensional slice of the levee. In addition, a few "typical" cross-sections may also be evaluated. However, a systematic attempt is not made to find cross-sections with low soil strength and the three-dimensional aspects of the problem are not considered.

The failure problem of levees is analogous to the problem of a long rod subjected to an axial load F. The rod has a cross section, A, which varies randomly along the length, and has a unit strength, f_y, which also varies randomly along the length. The combination of geometry and strength is then the determining factor of whether the rod yields or not at any point, x. The probability of yield for the entire rod length, given the load F, is then:

$$P_F = \text{Prob}\left[F \geq \min_{\text{for all } x} (A(x)f_y(x))\right]$$

If the load F is also a random function of x (disregarding the issue of equilibrium) then the probability of yield becomes:

$$P_F = \text{Prob}\left[1 \geq \min_{\text{for all } x} \left(\frac{A(x)f(x)}{F(x)}\right)\right].$$

In the case of a levee slip failure, the random variables include the average shear strength, $\bar{S}$, over the slip surface, the area of the slip surface, A, the radius of rotation, R, and the driving moment (assuming a circular arc surface), M. These variables are not only a function of the location along the levee, but also the geometry of the cross section, the unit weights of the materials, and the angle of internal friction. Thus, the probability of slip failure is:

$$P_F = \text{Prob}\left[1 \geq \min_{\text{for all } x} \left(\frac{\bar{S}AR}{M}\right)\right].$$

2.1.3 Mechanical

Although they are not considered to be in the realm of failures due to natural causes, mechanical (and/or electrical) failure of drainage structures, closure structures, and pumping plant equipment have been identified (Ref. 2-1) as one of three major failure types. These devices are similar to other mechanical or electrical equipment and are subject to operation and maintenance requirements. The reliability and availability of these items during flood events must be included in the overall system reliability model.

2.2 Causes of Failure

Many failures have been associated with circumstances or mechanisms outside conventional theoretical analysis. Most of these failures occur not because of the inadequacies in the state of the art, but because of oversights that could have been avoided, or poorly understood phenomena. The probabilities of failure of levees could decrease if the causes not easily analyzed were dealt with rationally by acknowledging and quantifying the uncertainty involved.

2.2.1 Flood Depth

Although there is no consistent rational basis for doing so, most levee systems in the United States are designed to withstand the 100-year return period flood stage without overtopping. However, the 100-year return period flood cannot be predicted with certainty. This is due to a number of factors. The first is the definition of the 100-year flood. One hundred years is the return period or recurrence internal for this flood level and is defined as the average number of years within which this event will be equaled or exceeded. Since it is only the average number of years, there is approximately a 33 percent chance that the "true" number of years is less than 100.

Other factors which must be considered in predicting a given flood stage are hydrologic and hydraulic uncertainty. Hydrologic design is generally based on past events and any attempt to predict future events must be based on probability. Haan (Ref. 2-2) has pointed out the the hydrologic probability model may be rainfall input to a hydraulic model, to predict runoff, or a flood level frequency curve based on historical stream flows. In the former, not only is there hydrologic uncertainty, but hydraulic modeling uncertainty as well.

To calculate the exceedance probability requires that the engineer select a probability model for maximum floods. Very often this distribution is assumed to be either the extreme-value type I distribution or the log-Pearson distribution, fit to the available historic data.

Uncertainty exists in selecting the underlying distribution parameters, since the recorded data are only a sample of the population, and the sample statistics (average and standard deviation and coefficient of skewness) are only point estimates of the "true" population mean and standard deviation and coefficient of skewness.

The traditional engineering approach for considering uncertainties is to develop confidence limits on the "true" model parameters, and then assume an arbitrarily conservative value for each parameter based on a preselected confidence level. This approach has a serious drawback, however, in that it results in the use of design values associated with unknown levels of conservatism.

A more rational approach for considering uncertainties in predicting maximum floods is to treat the "true" parameters as random variables (more precisely, as functions of random variables, namely the maximum annual floods) with a distribution function f(θ) which may be updated by gathering data (i.e., flood stage data for n years) and using Bayes' theorem (Ref. 1-6 and 2-3). Knowing the distribution of the model parameters, the unconditional exceedance probability for maximum annual flood magnitude, x, is computed using the total probability theorem:

$$p_X = P[X \geq x] = \int_{\text{all } \theta} P[X \geq x | \theta] f(\theta) d\theta .$$

In words, the conditional probability, $P[X \geq x|\theta]$, which is computed using the assumed probability model, with parameters θ, is multiplied by the probability of those parameter values actually being the "true" values, and this product is summed over all possible values of the "true" parameters.

The joint distribution of the parameters may be based solely on subjective judgment, if there is no recorded data, or it may be the result of combining the sample likelihood function (likelihood of observing the recorded data) and a uniform or other prior distribution. In this latter case, the posterior distribution of the model parameters (the one which is used to compute the exceedance probability) is the product of three factors:

$$\left(\begin{array}{c}\text{Posterior distribution}\\ \text{of parameters, given}\\ \text{the recorded data}\end{array}\right) = \left(\begin{array}{c}\text{normalizing}\\ \text{constant}\end{array}\right)\left(\begin{array}{c}\text{Sample likeli-}\\ \text{hood, given}\\ \text{parameters}\end{array}\right)\left(\begin{array}{c}\text{Prior distri-}\\ \text{bution of}\\ \text{parameters,}\\ \text{without knowing}\\ \text{the recorded}\\ \text{data}\end{array}\right)$$

or $$f''(\theta) = NL(\theta|x_1, \ldots x_n)f'(\theta), \qquad \text{for all } \theta.$$

The normalizing constant, N, insures that $f''(\theta)$ is a proper probability density function. Thus,

$$N = \frac{1}{\int\limits_{\text{all } \theta} L(\theta|x_1, \ldots x_n)f'(\theta)d\theta} .$$

The sample likelihood function is a function of the model parameters, θ, and is written:

$$L(\theta|X_1 = x_1, \dots x_n = x_n) = \pi_{i=1}^{n} f(X_i = x_i|\theta),$$

where $f(X_I|\theta)$ is the assumed underlying distribution of maximum annual floods. For example, if the distribution were assumed to be extreme-value type I (Gumbel), then the likelihood function would be written:

$$L(m_X, \sigma_X|x_1, \dots x_n) = \pi_{i=1}^{n} \alpha\exp\{-\alpha(x_i-u) - \exp[-\alpha(x_i-u)]\},$$

where $\alpha = 1.282 / \sigma_X$, and $u = m_X - 0.450\sigma_X$ (Ref. 2-4). The model parameters, m_X and σ_X are uncertain.

Assuming a log-Pearson distribution, there would be three model parameters to consider, m_Y, σ_Y, and γ_Y (coefficient of skewness), where $Y = \ell n(X)$, and X is the maximum annual flood. The sample likelihood function for a log-Pearson probability distribution is written:

$$L(m_y, \sigma_Y, \gamma_Y|y_1, \dots y_n) = \pi_{i=1}^{n} \frac{1}{|\beta|\Gamma(\alpha)} [(y_i-c)/\beta^{\alpha-1}\exp(y-c)/\beta],$$

$$\text{for } c \leq y_i < \infty \quad (\beta > 0),$$
$$-\infty < y_i \leq c \quad (\beta < 0),$$

where

$$\alpha = (2/\gamma_y)^2,$$
$$\beta = \sigma_y\gamma_y/2,$$
$$c = m_y - \frac{2\sigma_y}{\gamma_y},$$

and $\Gamma(\cdot)$ is the gamma function.

If the probability of exceeding the maximum annual flood magnitude, x, in any one year is p_x, then the probability of nonexceedance in one year is $1 - p_x$, and the probability of nonexceedance in m years is written:

$$P_x[NE_m] = (1-p_x)^m$$

Solving for m, the number of years for which there is a probability $P_x[NE_m]$ of not exceeding flood level x,

$$m = \ln(P_x[NE_m])/\ln(1-p_x)$$

Conversely, the magnitude of the design maximum annual flood, x, corresponding to a specified probability of nonexceedance in a specified number of years, m, is found first by solving the above equation for p_x:

$$p_x = 1-(P_x[NE_m])^{1/m}$$

Once p_x is picked a trial and error procedure is used to determine x from the unconditional probability.

Tang and Yen (Ref. 2-5) account for model uncertainty by introducing a multiplicative factor which has a mean and variance. Unfortunately, no data is available regarding the variability of this factor, and therefore the level of uncertainty is subjective. Although, intuitively, we believe that the fewer simplifying assumptions used in the adopted formulation the less uncertainty in the model there will be.

Uncertainty in flood discharges can be translated into corresponding uncertainty in flood stage using standard hydraulic techniques. Stream reaches with a high degree of hydraulic sensitivity (i.e., relatively great changes in stage results from a relatively small change in discharge) will have a greater tendency for levee overtopping than less sensitive ones.

Other factors that must be assessed in the evaluation of the hydraulic uncertainty are the potential and magnitude of debris or sediment accumulation or ice jamming during the discharge event. Sources of debris, sediment, and ice in upstream areas should be considered, as well as any historical evidence of ice or debris blockage or sediment deposition. The behavior of such materials within the leveed reach, and particularly at bends or constrictions, must be considered.

Flood stages for a given flow can change over time due to a variety of factors, and any change will alter the hydrologic risk. Changes affecting flood stage include:

- increased land use change that results in increased runoff volumes, shorter times of concentration, and greater peak discharges for events having the same meteorological characteristics;

- removal of natural valley storage and conveyance due to excess encroachment in floodplains, including construction of levee systems, resulting in higher stages and discharges;

- construction of reservoirs that modify the flows so that historical records cannot be used for current risk assessment without hydrologic reanalysis;

- changes to river bed or bank geomorphology or vegetative cover that significantly alter stage-discharge relationships and flood elevations.

2.2.2 Flood Exposure

Even though levees are generally designed such that the probability of overtopping is small, levees exposed to flood stages lower than the crest for long durations are susceptible to damage and even failure due to loss of stability, underseepage, sand boils, and wave erosion. Bogardi (Ref. 2-6) introduced the concept of "flood exposure" to take account of the combined effects of flood stage and duration on levee systems. He defined flood exposure as the area under the hydrograph of high water stages exceeding a specified limit, usually the toe elevation (for dry levees). At times of high water stages the following adverse phenomena have been observed along flood levees:

- saturation, loss of stability;
- underseepage and leakage;
- boil formation;
- wave erosion.

Saturation occurs generally by seepage below and laterally through the levee body by increased hydraulic pressure. Responding on the relative permeabilities of the levee material and substrata, seepage will occur either more rapidly through the levee material, in which case stability is weakened and leakage is common, or through the substrata, in which case underseepage and boil formation with possible crevassing on the landside of the levee is likely.

Flood exposure is the function of two random variables, flood stage and duration. To determine the resistance to such a load, it is necessary to perform stability analyses in which slope stability is calculated for a time dependent zone of saturation. Determining the transient motion of the zone of saturation in an embankment can be time consuming and difficult. An example from Reference 2-7 of the movement of the zone of saturation is shown in Figure 2-2a, with a typical saturation line secant-versus-time plot shown in 2-2b. A simplified approach appears to be in order for use in determining levee stability. The two main assumptions made in this approximation are:

- the time required for full saturation can be estimated, if permeability and porosity data are available for the levee, material;
- the shape of a moving saturation line in a homogeneous section is independent of the soil permeability, provided the permeability remains constant along the moving saturation line.

The shape of the zone of saturation may be determined from transient flow nets, and depends on embankment geometry, initial and final water depth, and initial phreatic surface. For our purposes it is adequate to model the moving zone of saturation as a straight line, making an angle with the riverside slope of the levee, as shown in Figure 2-3. The equation of line AB is given in terms of $\theta(t)$, α and d:

$$h(x, t) = \frac{x}{\tan\left[\theta(t)-\pi/2-\alpha\right]} + d$$

This equation assumes that the moving surface is a straight line rotating about point A.

From Reference 2-7 the time required for the saturation line to move through each incremental distance Δl is written:

$$\Delta t = \Delta l / v_{sl},$$

where: $v_{si} = ki/n_e$,

k = permeability,

n_e = porosity,

i = average hydraulic gradient in the incremental distance, Δl.

The total time to complete the saturation is written:

$$T = \Sigma \Delta t = \frac{n_e}{k} \Sigma \frac{\Delta l}{i} .$$

Using this method, Cedergren (Ref. 2-7) developed a graph for approximating the time of saturation of earth structures in the general shape of a levee or dam (see Figure 2-4). The chart shown in Figure 2-4 is based on an effective porosity of 0.25 and h = 1 foot, and neglects capillarity. To estimate the time of saturation of a levee, the time determined from Figure 2-4 is multiplied by the height in feet of the final water stage above the initial water stage. Note that in order to apply this procedure to the levee problem in the manner described, it is necessary to make the following approximations:

- the initial phreatic surface acts as an impervious surface and motion of the saturation line is as shown in Figure 2-3;
- the length, L, is measured from the point where the initial water stage intercepts the riverside slope to the landside toe of the levee.

Stability of the levee at any time after the onset of a flood exposure event can then be determined.

Immediately following a flood event for which a rapid decrease in flood stage occurs, stability of a levee may be compromised due to the changing shape of the zone of saturation. During a rapid drawdown, the saturation line may be obtained by the transient flow-net method (Ref. 2-7), which considers a succession of transient flow nets. Browzin

(Ref. 2-8) proposed a mathematical model of the time dependent nature of the saturation line shown in Figure 2-5. The proposed relationship is written:

$$t_H = \frac{cn_e}{2k} L\ C_1\left(\frac{H_1}{H}\right) + C_2 \ln \frac{H}{H_1} + C_3 \left(1 - \frac{H}{H_1}\right),$$

where n_e = effective porosity,

k = coefficient of permeability,

and coefficients C_1, C_2, and C_3 are found from Figure 2-6. The factor c is introduced to correct possible biases resulting from assumptions made, and ranges from about 0.9 to 1.4. The shape of the saturation line is assumed to be elliptical, so that:

$$\frac{h^2}{H^2} + \frac{x^2}{a^2} = 1 .$$

Solving these equations at time, t_H, after the end of a flood exposure event will allow us to determine the stability of the levee as a function of time.

If the levee fails, flooding of the protected area would happen only if a second flood event occurs before the levee is repaired. Otherwise, this type of failure would not be the cause of flooding.

2.2.3 Erosion

2.2.3.1 External Erosion

External erosion of levees is generally caused by either wind-wave action, or flow velocity (scouring). In the case of wind-wave action Bogardi (Ref. 2-9) describes the hazard to the levee in terms of a critical degree of protection. The following development of the distribution function for this load is from Reference 2-9.

The flood stage, h_1, and the additional wave effect, h_m, result in the total height, h_T. The value, h_m, is composed of the wave height due to wind plus run-up on the slope. The task is to determine the distribution function of the random variable, h_T, where:

$$F(h_T) = F(h_1+h_m) \ .$$

The model assumes that the random variables, h_1 and h_m, are independent. The distribution function of the annual highest stages, h_1, is assumed to be known and available from characteristic stream gauges. For the calculation of wave effect, h_m, the basic relationship is the following:

$$h_{m_i} = f(D_i,\ v_i,\ \tan\alpha,\ \cos\beta), \qquad \text{(See Figure 2-7)}.$$

Therefore, referring to the notation given in Figure 2-7, the wave effect on the cross section due to the wind having direction S depends on the corresponding fetch length, D_i, wind velocity, v_i, angle of levee slope, and the angle between the tangent of the levee and the examined direction. For the sake of simplicity only the most important variables have been mentioned.

In practice, the inundation area along the flat-slope reaches of large rivers is several kilometers wide. For these conditions the flood wave peak may last several days and during this period the water level changes very little. This justifies approximating the stochastic flood wave hydrograph by a constant peak value of random duration. Obviously, the highest waves occuring during this period may create the critical erosion situation.

From past records covering several years of wind measurements of the meteorological stations situated in the vicinity of the investigated levee section, maximum wind velocities for different directions (for instance for the eight main directions) and for different durations could be used. According to the above relationship, the maximum wave effect for different directions can be calculated for the critical period. The highest of these gives one sample element of h_m. Naturally, the probability of the yearly highest waterlevels occurring in different months of the year should be considered and the distribution of the wave effect, corresponding to the monthly critical period should be weighted with the appropriate probabilities.

Other types of external erosion are caused by excessive stream velocity, unstable streambed, and channel configurations which contribute to water flows impinging on levees and causing scour. When bank protection is subjected to stable currents, then surface erosion will occur when the tractive force produced by flow velocity exceeds the critical tractive force for levee surface protection. In addition, waves caused by unstable streambed formations near the levee, or flow impingement on the levee produce uplift pressures in combination with stream velocity and can cause surface erosion when tractive forces are smaller than critical. Consequently, when bank protection is designed for flow velocity alone and significant waves occur along the bank, surface erosion may occur for flows substantially less than the design flow.

Scour may be the result of unforeseen circumstances. An example is given in Reference 2-10, which describes a levee failure caused by scour. Naturally carried sediments were deposited upstream of a channel inlet, and, subsequently, sediment-free water was delivered to a rather steeply sloped reach. This was responsible for general streambed degradation downstream of the channel. In addition, channel meandering resulted in flow impingement on the levee causing deep scour at the riverside toe. The angle of impingment was estimated to be approximately 25 degrees.

Wide streams which are free to meander will have points and angles of impingement which are uncertain and should be addressed in design using probabilities.

2.2.3.2 Internal Erosion

Turnbull and Mansur (Ref. 2-11) made the following observations regarding underseepage and sand boils:

- sand boils are the result of excessive hydrostatic pressure and seepage through deep pervious strata underlying levees - severity is dependent upon the water head, source of seepage, perviousness of substratum, and characteristics of the landside top stratum;

- there is a positive correlation between surface geology and location and occurrence of sand boils;

- seepage flow and hydrostatic heads landward of a levee can be estimated theoretically, from piezometric data, and a knowledge of the foundation conditions.

Failure due to seepage is progressive. Seepage under or through a levee applies pressure to the soil particles, and if the pressure is great enough to carry or lift the particles, a sand boil or piping of materials from below or within the levee occurs. Piping, or sand boiling, does not in itself constitute failure of the levee, however. Either slope instability or the phenomenon of crevassing must occur as a result of piping in order that a levee fail from seepage. Turnbull and Mansur (Ref. 2-11) made the statement that "although a number of levee crevasses have occurred as a result of critical substratum pressures and concentrated seepage in the form of sand boils or piping it is practically impossible to predict." If, however, data related to underseepage and crevassing does exist, it appears possible to predict the occurrence of crevassing probabilistically, given the occurrence of piping or sand boils.

A pre-flood event condition which also influences the occurrence of piping or boiling is the amount and availability of substratum storage capacity on the landside of the levee. If a large storage capacity is available and a flood occurs, there may be a lag time of several days before seepage problems occur, simply because the substratum storage volume must be filled before the pressure under the top stratum can be built up. By that time the flood may have dissipated. On the other hand, if the storage volume is already filled or nearly filled by previous storms, seepage related problems may be coincident with the present flood event.

Seepage flow and hydrostatic heads landward of a levee can be estimated from theoretical considerations, piezometric data and knowledge of the underlying strata. Obviously the accuracy of such methods dependens on the degree of uncertainty in the parameters used in the formulations and the sensitivity to those parameters excluded.

Not all factors which influence the seepage flow and pressure lend themselves to theoretical analysis. Some of these factors include stratification of the foundation, lense deposits, and nonuniformity of the top stratum. However, some of the influences which may be evaluated are as follows:

- semi-infinite unconfined aquifer (Ref. 2-12) - for a sudden rise in the water stage from an initial steady state level of H_0 to H_1 (See Figure 2-8a), the change in head at a point x away from the river bank is written:

$$h^2(x, t) = H_0^2+(H_1^2-H_0^2)\mathrm{erfc}\left(\frac{x}{2\sqrt{Dt}}\right) ,$$

where: $D = (k_f-h)/E$,

k_f = horizontal permeability of aquifer,

$h = 0.5\ [H_0 + h(x,t)]$,

E = specific yield of aquifer,

and erfc (•) is the complementary error function;

- finite unconfined aquifer (Ref. 2-12) - for a sudden rise in the water stage from an initial steady state level of H_0 to H_1 in the river (See Figure 2-8b), the change in head at a point x away from the river bank is written:

$$h^2(x, t) = H_0^2+(H_1^2-H_0^2)\{\sum_{n=0}^{\infty}(-1)^n[\mathrm{erfc}(\frac{2Ln+x}{2\sqrt{Dt}} + \mathrm{erfc}(\frac{2Ln+2L-x}{2\sqrt{Dt}})]\},$$

  where L is the horizontal distance from the river bank to the barrier boundary.

Another cause of internal erosion, and one which does not readily lend itself to analytical evaluation, is animal burrowing and activity (Ref. 2-13). Burrows of animals (squirrels, beavers, muskrats) in levees may increase seepage and provide a path for water to flow during high water stages.

2.2.4 Settlement and Subsidence

Levees depend to some extent on freeboard to compensate for the lowering of crest height due to settlement and subsidence. It was pointed out in Reference 2-1 that levees with minimal or no compaction, or where embankment or foundation materials are undrained or composed of materials of high compressibility, will often experience a significant amount of postconstruction settlement. This settlement can result in losses of freeboard as much as 15 percent of the total levee height. These settlement losses will contribute to increased chances of overtopping and/or stability problems.

Another very important hazard which causes failure of some types of levees (particularly levees protecting highly organic lands used for agriculture) is subsidence of the levee and protected areas. In one study of the Sacramento-San Joaquin Delta area (Ref. 2-14), subsidence rates for islands and tracts protected by levees is as much as three inches per year. These subsidence rates have resulted in protected lands being below normal water levels by as much as 10 to 20 feet, thereby increasing the pressure on levees significantly.

Primary causes of subsidence were found to be soil oxidation and shrinkage. Additional causes, some of which may be substantial in localized areas, are wind erosion, burning, man-caused compaction, removal of soil, geologic (tectonic) subsidence and withdrawal of gas or ground water.

2.2.5 Earthquake

Earthquake ground motion can cause sliding failure either as a result of the change in material mechanical properties by liquefying, and/or an increase in loading by imposing an addition driving force in the horizontal direction.

Other possible impacts on levees resulting from earthquake ground shaking include (Ref. 2-15):

- compaction and settlement of levees or foundations;
- lateral spreading of levees or foundations;
- slumping;
- ground cracking;
- lurching of levees;
- erosion or overtopping by earthquake generated waves (seiches).

The potential hazards caused by earthquakes are greatest during high water when levees are already under high stress. The likelihood of such a combination of events is greatest for wet levees in areas such as the Sacramento-San Joaquin Delta. However, Mississippi River levees during flood season are also vulnerable for extended periods of time.

2.2.5.1 Inertia Load

The acceleration of the soil in an earthquake is another potential source of failure. Conventionally, the soil is simply assumed to be accelerated and this is an added driving force. With levees, the possibility of site amplification and the influence of water entrapped in the levee must be considered. The site amplification analysis requires a first mode approximation for the levee as a shear beam above the soil level where the ground motion is assumed imposed. Levee profiles will in general involve relatively long periods for casual construction, such as found in the Sacramento-San Joaquin Delta. Engineered fills, such as earth dams, produce stiffer materials and thus shorter periods along with decreased ability to deform without cracking.

2.2.5.2 Liquefaction

At this time, the state of knowledge of liquefaction does not allow the definition of the volume of material that loses its strength through increase in pore pressure. Hydraulically placed sands, for example, can lose their strength (friction) with a sufficient level or duration of vibration or both. One measure of the potential to fail is the number of blow counts it takes to move a standard probe one foot in the field. In effect, if the soil is highly likely to liquify, the blows of the sampling device on the soil will indicate this potential and the number of blows per foot will be small.

Liquefaction is an "either-or" phenomenon; either it does or does not occur for a given earthquake motion at a given site. Apparently, only sandy soils are prone to liquefaction, and it must, therefore, be determined whether a site has susceptible soil.

Seed and Idriss (Ref. 2-16) and more recently Seed, Idriss, and Grango (Ref. 2-17) presented a simplified procedure for evaluating the liquefaction potential for sand deposits. The procedure expresses the ratio of the average cyclic shear stress, τ_h, developed as a result of earthquake ground motion to the effective over burden stress, σ'_o, in terms of the maximum acceleration felt at the site. The relationship is written:

$$\tau_h/\sigma'_0 \simeq 0.65 a_m \frac{\sigma_0}{\sigma'_0} r_d ,$$

where: a_m = maximum ground acceleration,

σ_o = total overburden pressure,

σ'_o = effective overburden pressure,

r_d = is a stress reduction factor varying from 1.0 at ground surface to 0.90 at 30 feet and 0.75 at 50 feet.

Values of this ratio are then correlated with site soil parameters, such as the corrected standard penetration test (SPT) data for sites which have and have not liquified during earthquake. The SPT data is the number of blow counts per foot of penetration at different locations and depths. The correlated blow count is written:

$$N_1 = C_N N,$$

where C_N = the correction factor as a function of overburden pressure,

N = Standard penetration test (SPT) blow count at the particular point in the field being investigated.

The SPT blow counts, N, which measures resistance to liquification, varies from point to point within a layer. This means that for a given earthquake load, portions of a layer may liquify, while other portions may not. A useful tool in the probabilistic slope stability analysis of a levee section or reach would be an estimate of the percentage of a layer which liquifies during a given earthquake event. If, for example, 50 percent of a layer liquifies during a particular ground motion, then the average shear strength of the whole layer for use in the slope-stability analysis would be halved.

The delineation between the soil resistance that is adequate, and that which is inadequate, to prevent liquefaction for a given ground motion is shown in Figure 2-9. This delineation was empirically developed from field observations. The line of demarcation between liquefaction and non-liquefaction is obviously not fixed and could be considered a random variable, with the line shown in Figure 2-9 simply representing a mean value relationship between the strength parameter, N_1, and the cyclic stress ration causing liquefaction.

The linear portion of the mean value relationship is written:

$$m_{N_1} = 87.7\tau_h/\sigma_0' \; .$$

Assuming a coefficient of variation of 0.20, the standard deviation of N_1 is:

$$\sigma_{N_1} = (0.2)(87.7)\tau_h/\sigma_0' = 17.5\tau_h/\sigma_0' \; .$$

With this information, field data on the distribution of SPT blow counts in a given layer, and the distribution of σ_0', the probabilities of various percentages of a layer liquifying may be estimated for a given maximum ground acceleration. For example, the probability of at least 50 percent of a layer liquifying given an earthquake ground acceleration, a_m, and effective overburden is written:

$$P[N_{1R(50)} - N_{1L} \leq 0 \,|a_{max}, \sigma_0'] = \int_{N_{1R(50)}}^{\infty} f(N_{1L} \,|a_{max}, \sigma_0') dN_{1L},$$

where $N_{1R(50)}$ = fifty percentile corrected blow count as measured in the field,

N_{1L} = the corrected blow count corresponding to liquefaction for a given ground acceleration.

One such field study determined that the distribution of SPT blow counts in a sand layer was such that $N_{1R(25)} = 7.56$, $N_{1R(50)} = 10.8$, $N_{1R(75)} = 16.2$, and $N_{1R(100)} = 41.0$. The mean value of N_{1L} for σ_o' equal to 1,640 pounds per square foot was estimated to be 11.9, with a standard deviation of 2.38. Assuming a normal distribution and an earthquake with $a_m = 0.2g$, there is a 99.97 percent chance that at least 25 percent of the layer liquifies. There is a 99.7 chance that at least 50 percent of the layer liquifies. There is a 94.6 percent chance that at least 75 percent of the layer liquifies, but there is only a 0.02 percent chance that 100 percent of the layer will liquify.

If earthquakes are a hazard to a particular levee system, then this type of information becomes a necessary building block in the overall seismic risk assessment.

3.0 STABILITY MODEL

3.1 Probabilistic Considerations

During the course of this study probabilistic stability models were developed for both circular arc and wedge-type landslide failures in three dimensions. The initial work on the probability model utilized a Corps of Engineers levee geometry (see Figure 1-1). Two levee profiles from Woodward Island in the Sacramento-San Joaquin Delta were also studied (Figures 3-1a and b). Woodward Island geotechnical investigations produced a large amount of soil and cross-section geometry data. These data included 10 cross sections with surface geometries and soil profiles, as well as phreatic surface locations. Data from numerous bore holes were obtained and the soil properties of each soil horizon were estimated from these data. Parameters for the Woodward Island soil horizons are listed in Table 3-1. The correlation of cohesion and the tangent of the angle of internal friction was not estimated.

The analysis of the bore hole data indicated that the variation in the parameters for each soil horizon is random. Data for each soil horizon were combined to obtain the estimated means and coefficients of variation listed in Table 3-1. The correlation of soil properties along the levee was estimated based on the assumption that each pair of data was jointly normally distributed with a correlation coefficient that decayed exponentially with the distance between the sample points. The sample likelihoods for each pair of data points were multiplied and the constant term in the exponential decay expression was determined by maximizing the sample likelihood.

Uncertainty in the estimate of this decay parameter is large, but not unreasonable, given the type of casual construction and rehabilitation of the Woodward Island levees over the past 100 years, or so. A second case study (Ref. 3-1) indicates smaller coefficients of variation to be characteristic of carefully controlled engineered construction.

A computer program was developed (see Appendix) which obtains the probability of landslide failure of given length along a levee. Characteristics of the program are discussed in Section 3.2. It is noted that this program was designed to provide reasonable estimates of failure probabilities for use in levee systems analysis. It was not developed to compete with various other computer programs which estimate safety factors in conventional geotechnical studies.

The probability model significantly extends that used by Vanmarcke (Ref. 3-1) by virtue of including, not only a cylindrical, but also an ellipsoidal shape of the slip surface. In addition, the model has the ability to consider wedge failures that do not include passive earth pressure, and includes possible hydrostatic and ground acceleration effects from earthquakes.

3.2 The Basic Three-Dimensional Model

The essential characteristics of the analytical model are shown in Figure 3-2, using levee Profile C, (Figure 1-1). A circular arc failure surface is assumed to exist perpendicular to the levee axis. The arc may intersect the soil on the riverside of the levee profile below the water surface so that hydrostatic load may exist. The arc of the circle can be made very large to approximate a wedge-type of failure. Note that this is not a general wedge failure analysis, since it does not include passive earth pressure influence at the toe. Single slices can be considered or the failure surface can be assumed to be either cylindrical or ellipsoidal in shape in the direction of the levee axis. The model also includes the possible influence of a horizontal acceleration to approximate earthquake effects through the use of a static coefficient.

For analysis, the levee is divided into segments, as shown in Figure 3-2. Slices through the levee are considered as shown. Each vertical prism of soil above the assumed failure surface is treated in turn in the analysis. A soil prism can contain up to five soil horizons. A horizon can be damp, saturated, or a damp portion can occur above a saturated portion as defined by the phreatic surface. The mean and variance of soil density (damp and saturated), cohesion, tangent of the angle of internal friction, and the influence of pore pressure are considered in the analysis for each horizon in accordance with Lambe and Whitman (Ref. 3-2). It is assumed that during failure all segments are fully mobilized along the failure surface so that the block of soil initially moves as a rigid body.

The simplicity of the model is advantageous in that it allows the consideration of both circular arc failures and wedge-type failures in one model for several conditions, including hydrostatic loads, horizontal acceleration loads, variations in the phreatic surface, variations in geometry, rapid drawdown, and failures in both the riverside and landside faces.

A mean safety factor and a probability of failure assuming that the random variable "safety factor" is lognormally distributed are computed for each analysis. Initial studies utilized a normally distributed safety factor; but when it was observed that the coefficient of variation of the safety factor was large for some soils (see Table 3-1), a change was made to the lognormal model.

Results of one such analysis are shown in Figure 3-3. Note that the probability of failure generally decreases with an increase in the mean safety factor, but there are exceptions. As a consequence of the increase in variance, the probability of failure can increase while the mean safety factor increases, and vice versa. It is also important to note that an infinite number of possible failure surfaces exist, each with its own probability of failure. The properties of the failure surfaces are highly correlated so that the most critical failure surface is the one with the largest probability failure, not the smallest mean safety factor. Many failure surfaces can sensibly have the same probability of failure. Thus, critical zones of failure exist rather than a single critical surface, or arc, as determined in conventional analyses. That is, if probabilities of failure are rounded-off to values consistent with the uncertainty in the data, many different failure surfaces have the same likelihood of failure.

Failure probabilities are conditional on the radii and centers of rotation of the slip surfaces. To find the unconditional probability of failure, the total probability theorem is used:

$$P[F] = \sum_{\text{all } i} P[F|S_i]P[S_i],$$

where S_i is slip surface, i. Although $P[S_i]$ is unknown, the unconditional probability of failure is just the weighted average conditional probability of failure, given S_i, and will always be less than the maximum conditional probability of failure:

$$P[F] \leq \underset{\text{all } S_i}{\text{Max}} P[F|S_i].$$

Therefore, a conservative and simple approximation to the probability of slip surface failure is to determine the maximum conditional probability by trial and error and use that.

The very large variability in the safety factor was also of interest. The coefficient of variation of the safety factor was on the order of 0.6 to 0.7 for the material properties listed in Table 3-1. This magnitude of the coefficient of variation precluded the use of the normal distribution to model the safety factor. Note that the coefficient of variation of the safety factor was dominated by the coefficient of variation of cohesion.

Using the developed model, the analysis of a levee section consists first of a search of possible centers of slip and radii based on a single slice. The analysis then considers the extent of failure. Typical results are shown in Figures 3-4 and 3-5. The most likely failure length is one of the basic results of this type of analysis.

Vanmarcke (Ref. 3-1) used level crossing theory in examining the extent of failure. This study uses the concept of a critical length. The critical length is defined as that length beyond which correlations essentially need not be considered. If a levee is 5,000 feet in length and the critical length is 1,000 feet, then five critical lengths exist in the levee and five Bernoulli type trials may be considered in estimating the landslide failure probability of the 5,000 foot system. The critical length is necessarily subjectively defined, but it is a useful intuitive approximation in systems analysis because of its basic simplicity.

3.3 Sensitivity Studies

The analytical model is complex, and involves many parameters, depending on the number of soil horizons considered. It is, therefore, useful to examine the results of an analysis as a function of the properties of key parameters in an effort to identify the dominant ones as well as possibly reduce the amount of field data. The mean of a property is easier to estimate with adequate reliability than the variability. However, the coefficient of variation may be typical of the particular class of soil, while the mean varies and can be established with a few samples.

With the large number of parameters in even a profile with two layers, the sensitivity study was limited to levee Profile C with a cylindrical failure surface analysis and two soil horizons. Each soil horizon is characterized effectively by four parameters, the damp and saturated densities, the cohesion, and the tangent of the angle of internal friction. The difference between damp and saturated conditions for the latter two parameters was not considered. The objective of the sensitivity study was to investigate the influence of different levee variables, as well as the variability of each of the soil parameters on the mean safety factor and probability of failure, since it is the most difficult value to estimate. Landside subsidence conditions and varying phreatic surfaces were considered.

3.3.1 Influence of Soil Parameter Variability

As expected, the shape of the failure probability curves is not altered by changes in the coefficients of variation of the soil parameters. The coefficient of variation of the cohesion had a significantly larger influence than those of the other parameters. This is consistent with the observed influence of the cohesion on the safety factor for the soils considered.

The influence of the coefficient of variation of cohesion on the probability of failure is shown in Figure 3-4. Here, all other coefficients of variation are equal to 0.2. Similarly, the influence of the coefficient of variation of the tangent of the internal friction angle is shown in Figure 3-5. The dominance of cohesion in the strength properties of the levee materials is shown by the relative magnitudes of the probability of failure.

In summary, the influence of a change in the coefficients of variation of all the other soil parameters (density, friction) was less than that of cohesion.

3.3.2 Influence of The Phreatic Surface

Studies were made of the influence of the phreatic surface using levee Profile C (Figure 1-1). In the first set of analyses, the phreatic surface was located at five different levels, from the crest of the levee on the riverside to below the levee in the subsoil, as shown in Figure 3-6. The soil properties for the levee horizons are given in Table 3-2.

Analyses were made assuming both cylindrical and ellipsoidal failure surfaces, as discussed in Section 3.2. The probability of landslide failure and its corresponding mean safety factor were calculated as a function of phreatic surface location and failure length measured along the levee.

The steady state influences of phreatic surface location are shown in Figures 3-7a,b,c, and d. The assumption of a cylindrical failure surface are depicted in Figures 3-7a and 3-7b. Probabilities of failure are seen to be very sensitive to the location of the phreatic surface, whereas the mean safety factor is relatively less variable. Note that the probabilities of failure are on a logarithmic scale in Figures 3-7b. End zone contribution to the total resisting moment is seen to decrease with increase in rupture lengths. Similar results were obtained assuming an ellipsoidal failure surface, Figures 3-7c and 3-7d. Note that the zone of "most likely" failure length is narrower with an ellipsoidal failure surface than with a cylindrical failure surface and that this zone broadens greatly for higher phreatic surfaces.

The influence of a rapid rise in the phreatic surface was also studied. If, for example, the water level rises rapidly from elevation 7.3 feet to 18.2 feet as shown in Figure 3-8, the phreatic surface as a function of time can be approximated by several straight lines. Analyses were made of the probabilities of failure and safety factors for both cylindrical and ellipsoidal failure surfaces. The results are shown in Figures 3-9a,b,c,and d. Note that the time between initial and final phreatic surfaces depends on the permeability and geometry of the cross section.

3.3.3 Influence of Landside Subsidence

To study the influence of subsidence on failure (using a cylindrical failure surface), analyses were made with two different phreatic surface conditions and five landside subsidence conditions. The geometry configurations used are shown in Figure 3-10a and the results of the analyses are shown in Figures 3-10b,c,and d. The probability of failure for maximum subsidence was almost 50 percent greater than for the original configuration.

3.3.4 Riverside and Crest Erosion

Studies of levee slope stability as a function of both riverside and crest erosion were made using levee Profile C. The water surface was assumed to be at the top of the levee. The crest erosion conditions considered are shown in Figure 3-11. It was found that the effect of both riverside and crest erosion on the probability of failure was minimal. This is intuitively obvious in the sense that a change of between 0.5 and 1 foot near the center of a 20 to 30 foot high earth structure or on one face will not significantly affect any of the terms in the resisting moment or driving moment equations.

3.3.5 Rapid Drawdown

Two different phreatic surfaces (Fig. 3-12a) were assumed prior to a rapid drawdown in order to examine riverside levee slope stability. Levee Profile C (Figure 1-1) was used in the analysis along with a cylindrical failure surface. Drawdown was analyzed in accordance with Reference 3-2. The results of the analyses are shown in Figure 3-12b, and c. The relatively high probability of failure due to a complete drawdown condition shows why it is cause for concern in geotechnical engineering. The difference in "most likely" rupture lengths is due to the greater coefficient of variation in the safety factor for the higher phreatic surface.

3.3.6 Horizontal Earthquake Acceleration

The influence of a horizontal earthquake acceleration of 0.05g on levee Profile C was studied using both a cylindrical and an ellipsoidal failure surface. Four different phreatic surface conditions were considered (Figure 3-6). The analysis was accomplished by a slight modification of the computer program to include horizontal inertia forces from each segment of each soil column in the soil mass. The inertial effects of the water on the riverside face of the levee were not considered.

The results of the studies are shown in Figures 3-13a and b for the two failure surface assumptions. The effect of an earthquake acceleration is to increase the probability of failure for the different phreatic surfaces by an almost constant amount. The probability of failure approximately doubles and the mean safety factor is reduced by a factor of about two as a consequence of a 0.05g horizontal acceleration.

3.4 Comparison of Present Study with Vanmarcke's Methodology

As a check on the developed analytical methodology, an example presented by Vanmarcke (Reference 3-1) was studied. The methods differ in the correlation decay function, but are otherwise similar. Vanmarcke assumed an exponential decay using the square of the distance between locations, while this study assumes a linear relationship with distance in the exponential decay. The difference between the two decay functions is not large from a practical point of view, since the two functions employ different coefficients. The analytical model employed in the present study also includes a further linearization of the influence of correlation of material properties.

The levee profile used in the comparison is shown in Figure 3-14a and the soil properties are given in Table 3-3. The first analysis was made without a phreatic surface (drained levee condition) using a cylindrical as well as an ellipsoidal failure model. A conventional slip-circle analysis was also made. The mean safety factor was computed at 1.17.

Using the data presented in Table 3-3 and a 250 foot long cylindrical failure surface, the mean safety factor was found to be 1.21, and the probability of failure was calculated to be 0.090. This probability is compared to 0.086 calculated by Vanmarcke. Using an ellipsoidal failure surface and a rupture length of 300 feet, the probability of failure was 0.049 and the mean factor of safety was 1.30. Figure 3-14b is a plot of the probability of failure versus failure length for the two failure surface assumptions. Figure 3-14c contains a similar plot for mean safety factor.

3.5 Woodward Island Studies

Limited analytical studies were made for two levee cross sections of Woodward Island. The geometries are shown in Figures 3-1a and b. The soil properties for both sections were assumed to be the same for the same soil horizons.

The first part of this study examined the influence of the soil property variations on the safety factor and the probability of failure. As expected, it was found that the most critical failure surfaces, as defined by the largest probability of failure, depended on both the mean safety factor and the variability of that factor so that the critical failure surface was not necessarily associated with the minimum safety factor.

Although the minimum safety factor may not define the "most likely" failure surface, it is important to note that a failure zone exists in which many surfaces have very similar failure probabilities. This being true, from a practical engineering point of view, it is not necessary to determine the mathematically critical surface, since any arc in the broad failure zone will have sufficiently similar properties for engineering purposes.

Typical analytical results are shown in Figures 3-15a,b,c, and d, in which the mean safety factor and the probability of failure are plotted against failure length. It is seen that the influence of the flood level, on the mean safety factor is much smaller than it is on the probability of failure.

The probability of wedge failure along the base of the levee had an extremely small value, beyond the range of validity of the basic data.

3.6 Conclusions

- The levee length beyond which correlation influences can be neglected is herein called the critical length. This length is based on the decay of the probability of failure with failure length. Each such critical length in a levee reach can be considered to be independent in response to the hazards or loads. The critical length is a convenient approximation in the analysis of system performance.

- A "most likely" failure length exists in each critical length of levee, but this length is not sharply defined. Many lengths have about the same probability of failure. Similarly, a wide variety of slip-surface descriptions have about the same probability of failure. A shorter "most likely" failure length zone is associated with an assumed ellipsoidal failure surface, while a longer length is associated with a cylindrical failure surface.

- The probability of failure is a better index of safety than the safety factor, if the slip surface penetrates through soils with differing properties and large variabilities. The difference in characteristics between an ellipsoidal and a cylindrical failure surface depends on the soil properties. Differences are more pronounced with highly variable soil horizons.

- Small variations in levee geometry have a minor influence on stability.

- Small variations in the location of the phreatic surface have a minor influence on levee performance. Large variations in phreatic surface, as induced by a long term increase in water level or a rapid drawdown, result in major increases in the probability of failure.

- Sensitivity studies indicate that the variability of the safety factor and thus the probability of failure in these studies is dominated by the large variability of the cohesion. Minor variabilities can be neglected. It appears likely that the coefficient of variation of soil properties can be estimated subjectively from two factors, the natural variability of the soil and the degree of control evidenced in levee construction. Casual construction is associated with much larger coefficients of variation than carefully controlled engineered construction.

4.0 Systems Analysis and Scenarios

4.1 Systems Analysis Applied to Levees

Levee systems consist of components, such as embankments broken down into subreaches), hardware (e.g. closures, pumps, etc.), and operation and maintenance personnel. The system is surrounded by a physical and social environment, and suffers from aging.

Henley and Kuromoto (Ref. 4-1) point out that there are two basic approaches for analyzing causal relations in a systems analysis: forwards and backwards. Forward analyses start with failure events and try to identify all possible consequences. Failure events are generally related to:

- human error, such as design error, operator error, maintenance error or neglect;
- materials problems, such as low strength;
- the environment, such as earthquakes, subsidence, animal burrowing, flooding, etc.

On the other hand, backward analyses begin with a possible system failure (e.g., levee breach) and trace backwards searching for possible causes.

Event and decision trees are forward analyses, whereas backward analyses are typified by the fault tree. Generally, both of these approaches are used cooperatively to attain a complete systems reliability analysis. The backward analysis is used to identify the causal relationships leading to a specific failure, the failure being the top event of the fault tree (levee breach). The forward analysis assumes different sequences of events and specifies a number of scenarios ending in the system failure. The information which must be developed in order to write good scenarios are component layout, component failure characteristics and system specifications.

Component failures are classified as primary failure, secondary failures, or command faults. A primary failure occurs when a component is in a non-working state caused by natural aging (e.g., erosion, subsidence, etc.) and in need of repairs to return to the working state. A primary failure may occur at loads below the design allowable load condition. A secondary failure is the same as a primary failure except that the failure is due to excessive demands caused by such events as earthquake, water stages greater than the design flood level, etc. In the terminology of fault tree analysis, primary and secondary failures are known as basic failures. Note that these failure classifications may be dependent. For example, if an earthquake shakes a levee whose material strength has been weakened over the years by rodents, or eroded by wave action, then the failure is a combination of primary and secondary events.

A command fault is defined as a component being in the non-working state due to improper operation. For example, a closure is not closed in time to prevent a less than design flood from inundating behind a levee, or a closure is inadvertently closed causing water from a tributary behind a levee to flood the protected area.

An example of how multiple, dependent hazards can be handled for a levee is given by Duckstein and Bogardi (Ref. 4-2). They present a methodology for determining the reliability of levee systems which takes into account four types of failure hazards: overtopping, subsoil failure (boils), slope stability, and erosion. The loads include peak flood level, duration, and volume. The flood height can be assumed constant but random at all sections, or varying according to backwater effects and wind waves.

The resistance of each section is then determined for each of these loads and is expressed in terms of the flood parameter that triggers the failure. Resistance values are determined by direct measurement (levee profiles, soil properties) and analysis (seepage, stability). In general, the flood parameters governing these four types of failure are different.

The reliability model outlined in Reference 4-2 takes into consideration the stochastic character of the flood load, the random resistance of each section of the levee reach, and the different modes of failure. Failure of a levee section occurs if either:

$h > H_1$: overtopping,
$h > H_2$: subsoil failure (boils),
$h > H_3$ and $w > W$: slope stability failure,
$h + x > X$: wave erosion,

where
h = peak flood level,
w = flood exposure (the area of the stage hydrograph),
x = wave height and run-up,
H_1 = crest height,
H_2 = flood height corresponding to onset of boils,
H_3, W = respectively, the smallest <u>necessary</u> flood height and the largest <u>allowable</u> flood exposure for slope stability failure,
X = the highest dynamic water level (peak static level + wave + run-up) necessary for erosion failure.

The failure event is for a given levee section written as:

$$F = [h > H_1] \cup [h > H_2] \cup [h > H_3 \cap w > W] \cup [(h + x) > X].$$

For ease of computing the failure probability the failure event can be divided into disjoint events:

$$F = A \cup B \cup C \cup D,$$

where
$$A = [h \leq H_3] \cap [h + x > X)],$$
$$B = h \geq \min [H_1, H_2],$$
$$C = [H_3 < h \leq \min (H_1, H_2)] \cap [h + x > X],$$
$$D = [H_3 < h \leq \min (H_1, H_2)] \cap [h + x \leq X] \cap [w > W].$$

Subdividing the levee into subreaches, each with its own failure event defined, the system failure event is then defined as:

$$F = F_1 \cup F_2 \cup . . . \; F_n.$$

Letting
$$H = \min (H_{1,i}, H_{2,i}),$$
$$H_3 = \min (H_{3,i}),$$
$$t = \min (W_i), \qquad \text{for } H_{3,i} < h < H,$$

the conditional probability of failure of the levee system, given H, H_3, and t, is written:

$$P_{F|H,\, H_3,\, t} = 1 - F_h(H) + \int_{H_3}^{H} \int_{t}^{\infty} f(h, w)\,dw\,dh.$$

4.2 Scenarios in Levee Systems Analysis

Scenarios are simply a series of events that we imagine happening in the future. We construct scenarios in our every day lives, but rarely are they as developed or elaborate as those prepared by researchers working for the government or industry for military, political, and economic forecasting.

The term "scenario writing" denotes a technique which attempts to set up a logical sequence of events in order to show how, starting from the present (or any other given) situation, a future state might evolve, step by step. For the purposes of technological forecasting, time does not always have to be introduced explicitly, but may only be intervals of time, such as one year, ten years, etc.

Scenario writing is particularly suited to dealing with several aspects of a problem more or less simultaneously that may be interrelated. By the use of a relatively extensive scenario, the analyst may be able to get a "feel" for events and for the branching points dependent upon critical choices. These branches can then be explored more or less systematically.

Scenarios force the analyst to deal with details and dynamics which he might easily avoid treating if he restricted himself to abstract considerations. Typically, no particular set of the many possible sets of details and dynamics seems especially worth treating, so none are treated, even though a detailed investigation of even a few arbitrarily chosen cases can be helpful.

Various methods have been employed to structure scenarios, including morphological analysis, event-tree analysis, cross-impact analysis, brainstorming, etc., and yet the one which appears to be most useful to decision makers regarding levee systems is the event tree. Not only can environmental events be constructed, technological events and consequential events can also be evaluated.

5.0 CONSEQUENCES AND DECISION MODELING

5.1 Consequences

Flooding is natural. However, when flooding comes in contact with developed areas, losses occur. Efforts to mitigate flood losses take many forms including flood-plain construction of levees. Flood-plain management should undertake to minimize the costs associated with flood-plain occupancy by optimizing the initial cost of development, the cost of flood protection, the cost of residual flood damage, and the cost of relief and rehabilitation.

Tangible benefits from flood mitigation include prevention of flood damage and land enhancement from more intensive use of protected land. The primary benefit from prevention of flood damage is the difference in expected damage throughout the life of a land use project with and without flood mitigation. Primary benefits include decrease or elimination of:

- costs of replacing or repairing damaged property;
- costs of evacuation, relief, and rehabilitation of victims, and emergency flood-protection measures;
- losses resulting from disruption of business;
- loss of crops, and/or cost of replanting crops.

Unfortunately, levee constuction activities often encourage over-development in flood hazard zones, thereby increasing the potential consequences when and if a levee is breached or overtopped during storm run-off.

Reference 5-1 states that there are approximately 160 million acres of land in flood plains, with more than 6 million dwellings and structures. In a recent six-year period there occurred 193 major natural disasters, of these approximately 80 percent involved flooding. It has further been estimated (Ref. 5-2), that levee overtopping or failure is involved in approximately one third of all flood disasters. In 1978 the total flood damage was estimated at 3.8 billion dollars, and the average annual property loss during the 1970's was 1.7 billion dollars.

In an example of a single incident, a recent break in a Sacramento-San Joaquin Delta levee flooded 6,100 acres of prime farm land to a depth of twelve feet, causing an estimated direct loss of 10 million dollars (Ref. 5-3). The cost of closing the breach and dewatering the protected land was estimated at 6.6 million dollars, with a crop loss estimated at 3.25 million dollars. It was further estimated that 210,000 tons of quarry rock and 340,000 cubic yards of silt will be required to close the 600 foot long by 85 foot deep breach.

In addition to the direct consequences of property damage and repair costs, there are many indirect consequences which should not be overlooked in the overall flood mitigation decision process. For example, a similar break in another Delta levee caused 11,000 acres to be inundated by 150,000 acre-feet of water (Ref. 5-4). The inrushing water allowed salt water to encroach on the Delta from Suisan Bay. In an attempt to flush the salt from the Delta, since many communities rely on the Delta waters for fresh water, state and federal water projects began to release additional fresh water from surrounding reservoirs and curtailed fresh water pumping for consumption. Within ten days over 300,000 acre-feet of water were released from reservoirs in order to cleanse the Delta and restore the hydraulic barrier between fresh and salt water. Even with this large inflow of extra water, the Delta could not be entirely flushed and the bulk of the salt had to be removed over the next several weeks by pumping. In addition, unmeasurable damage was caused to the San Francisco and Delta fisheries, wildlife, and water users in southern California. Although the Sacramento-San Joaquin Delta is unique among levee systems, this example indicates that the consequences of levee failure may be felt by many diverse interests both near and far, and that the planning of new levees or rehabilitation of existing levees necessitates the inclusion of all consequences, not just the obvious ones.

5.2 Decision Making

Consequences are variable with magnitudes assigned probabilities of occurrence. For example, the length and depth of a breach cannot be known ahead of time. Repair costs are a function of these dimensions and are, therefore, uncertain. Often, only the expected value of these consequences is estimated, with no indication of the variability in the estimate. For expected value decision making this procedure is adequate. However, if there is any degree of risk aversion in the decision making body, it is essential to estimate the variability, as well as the expected value.

The impact of the difference between expected-value decision making and risk-adverse decision making is illustrated in the following example. Suppose there are two different insurance situations the Federal Insurance Agency (FIA) can find itself in. The first is a situation in which the FIA is asked to issue flood insurance policies for a community of 10,000 homes which is protected by a levee designed to the 100-year flood (disregarding the geotechnical risk of failure at a lower level, the chance of overtopping is any year is 0.01). The probable number of times this community will be flooded in the next five years, for example, is governed by the binomial distribution. If a flood does occur in this community, all 10,000 homes will be flooded (the chance of this happening at least once in a five-year period is 0.049). If each is insured to 100,000 dollars, this represents a potential loss to FIA of 1,000,000,000 dollars. However, from an actuarial point of view, we find that the expected number of damaged homes over a five-year period is only 500, representing an expected monetary loss of 50,000,000 dollars. Thus, the actuarial premium should be 1,000 dollars per year on the average for each homeowner in this community.

In the second situation, the FIA is asked to insure homes in five separate communities, geographically independent from one another, each with 2,000 homes and each protected by a 100-year levee. In a five-year period, the probable number of times any one of these communities will be flooded is again governed by the binomial distribution. As with the first situation, if a levee is overtopped, all 2,000 homes in that community will be flooded. Therefore, over a five-year period the total expected number of damaged homes in the five communities is 500 with an expected monetary loss (assuming 100,000 dollars per home) of 50,000,000 dollars, just as in the first situation. However, the chance of flooding 10,000 homes or more in the five-year period drops dramatically to 0.000044.

Although there is a greater chance of some homes flooding in the second case (0.22 vs. 0.049), there is a much greater chance of sustaining catastrophic levels of monetary loss in the first case (0.049 vs. 0.000044). Therefore, a relatively new insurance program, such as the National Flood Insurance Policy (NFIP), with an unestablished reserve to cover the type of catastrophic loss represented by the first situation, should be adverse to the extreme risks implicit in the use of the expected monetary value approach.

The graph in Figure 5-1 shows two utility curves representing two different risk attitudes. The straight line represents an expected value utility curve and is the rational one to use if a large enough reserve were available. The curved line represents a typical risk adverse utility curve and is the type that should be used to establish insurance premiums for a new insurance program. If a risk adverse utility curve were adopted, it would mean that the insurance premiums in the first situation should be higher than the second situation, or that the required levee design level in the first situation should be more restrictive than in the second, or both. Requiring that the design level of the levee in the first case be such that the chance of the catastrophic loss is the same as in the second case would mean a design flood equal to the 100,000 year event. Economically, this may not make sense, and a more balanced solution would be more appropriate (also note that the uncertainty in determining the 100,000-year event is tremendous). In either case, if no flooding occurs over a period of years and the reserve is built up, the utility curve for NFIP approaches the expected monetary loss value.

A. APPENDIX

A.1 Levee Stability Computer Programs

These computer programs were developed on the Hewlett-Packard 85 and 86 computers in Basic language. Program SLOPE 86 inputs the levee geometry and horizon material properties. Program SEEK86EQX searches for the critical circle in a given levee configuration. Program SUPERSTB, calculates the probability of failure and corresponding safety factor for a levee with rupture length, L, for either a cylindrical or ellipsoidal failure surface. The programs SEEK86EQX and SUPERSTB have the capability to analyze hydrostatic and/or earthquake effects, the latter being accounted for by the inclusion of a horizontal load from a constant pseudo-earthquake acceleration.

The basic analytical methodology for determination of the mean factor of safety is simple and conventional, but several important assumptions of a probabilistic nature are made that need a brief explanation. First, in calculating the effective weight of a soil prism composed of several soil horizons and an estimated phreatic surface, the mean effective density of each successive layer from the top down to the failure surface is used as in conventional analysis. The variance of weight is simultaneously calculated from the mean density, the coefficient of variation of density, and the geometry with the additional assumption that the successive random variables (weight) are perfectly correlated. In the levees of primary interest, this appears to be a reasonable assumption, but there are no data to support the assumption of unity correlation coefficient.

The computations for each successive soil prism yield cohesion capacity along the inclined failure surface (mean and variance), friction capacity (by combining the mean and variance of with the mean and variance of the tangent of the angle of internal friction, assuming independence between the weight and the friction properties), and loading influence (mean and variance). The analysis involves a great many soil prisms and each has its own mean and variance for each of the above factors. For simplicity, it was assumed that the coefficient of variation of total mass was about the same for all prisms so that the mean coefficient of variation of all of the soil prisms could be used to characterize the entire soil mass. The problem here is one of unknown correlation of properties from prism to prism.

Owing to the large coefficients of variation of the soil properties, the safety factor was assumed to be lognormally distributed. With soils whose properties have a small coefficient of variation, of the order of 0.2, the safety factor can be assumed to be normally distributed.

Finally, some field data on the variation of soil properties along the levee were available. It was assumed that each test boring represented about 100 square feet in horizontal area or a square about 10 feet on a side. The correlation coefficient of soil properties between 10 foot square areas of soil was assumed to be of the form exp(-CX) in which C was taken to be 0.015, based on a maximum likelihood estimate using paired data. X is the distance between prisms in units of 10 feet.
